

Inflation Inequality Across the Euro Area¹

Erwan Gautier²

Jérémi Montornès³

August 20, 2026

Abstract

This article documents inflation inequality across household categories in the euro area using harmonized HICP prices and household budget surveys. We construct country-level inflation indicators by income, age, and residence area, aggregate them to the euro area, and assess recent fiscal interventions using counterfactual price indices. During the 2021–2023 inflation episode, the cumulative inflation gap between the first and fifth income quintiles was 0.9 point in the euro area. Over the same period, cumulative inflation for households aged 60 or over exceeded that for households under 30 by 1.3 points, while the cumulative rural–city gap was 1.0 point. Counterfactual indices indicate that household price policies, including tariff shields, VAT and charge cuts, fuel rebates, and price caps, lowered average cumulative inflation by 0.7 point and reduced the income-quintile inflation gap by 1.2 points in the 20-country aggregate.

Introduction

This paper examines the effect of the recent inflation surge on euro area households. Since mid-2021, inflation rates in the euro area have risen sharply, displaying considerable dispersion across countries and socio-demographic groups. Central banks target aggregate inflation, but the welfare cost of a given aggregate inflation rate is heterogeneous across households. High inflation disproportionately affects households whose consumption baskets are more exposed to rapidly rising prices, in particular households with higher expenditure shares on energy and food. The 2021–2023 episode was a large relative-price shock, initially driven by imported energy and commodity prices. Its incidence therefore mainly depended on household exposure to energy, including heating and transport ([Levell et al., 2024](#)).

We examine how recent energy-price shocks and the fiscal response shaped household inflation exposure across the euro area. We construct monthly inflation indices by income, age, and residence area for each euro-area country and aggregate them using Eurostat’s HICP methodology. We also use household-level expenditure records to measure within-group dispersion and construct counterfactual price indices that remove the main price-based fiscal interventions of 2021–2023.

Our main results are the following. Inflation inequality varies substantially across euro-area countries. Between June 2021 and June 2023, the cumulative Quintile 1–Quintile 5 gap reached several points in the Baltic countries and Ireland, but was small in France and Spain. In the euro area, the cumulative income gap was 0.9 point; the corresponding age and rural–city gaps were 1.3 and 1.0 points. The inflation burden was 3.1, 10.2, and 7.4 percent of net income for the first quintile in 2021, 2022, and 2023, compared with 2.0, 5.7, and 4.1 percent for the fifth quintile. Older and rural households experienced higher inflation during the rise in energy prices. In household-level regressions, age and residence are the strongest correlates during the energy shock. The rural–urban breakdown is large in 2021–22 but disappears in 2023, whereas the age gradient remains visible in 2022–23; the association with income changes sign over time. Finally, household price policies lowered average cumulative inflation by 0.7 point and reduced the aggregate income–quintile gap by 1.2 points. These policies reduced the contribution of gas and electricity to the income gap by 1.4 points, while their effect through fuel increased the gap by 0.2 point. A complementary input–output simulation shows how energy-sector disturbances reach households independently of the policy counterfactual: direct exposure accounts for 0.7 point of the simulated 1.0-point income gap, and indirect propagation through production networks accounts for the remaining 0.3 point. Together, these decompositions show that energy shocks generate inequality

both at the point of household purchase and upstream through firms' input costs, whereas the fiscal response primarily cushioned the direct household-energy channel.

The literature measures household inflation by combining price changes with differences in expenditure patterns. Early contributions reweight aggregate price indices for demographic groups (Hobijn and Lagakos, 2005), while studies using household-level expenditure or scanner data document substantial dispersion within those groups (Argente and Lee, 2021, Kaplan and Schulhofer-Wohl, 2017). More recently, Jaravel (2024) constructs distributional consumer price indices for the United States from official price data and group-specific expenditure shares. For Europe, Charalampakis et al. (2022) and Menyhert (2023) show that food and energy inflation raised the effective inflation rates of lower-income households, with substantial differences across countries. Pallotti et al. (2024) combines consumption, income, and balance-sheet channels to measure welfare losses across euro-area households. We instead isolate variation arising from consumption baskets and construct monthly indices by income, age, and residence area for all 20 euro-area countries. Unlike existing cross-country indicators, our group-specific baskets aggregate to official HICP item weights. Because we assign a common price index to all households within each COICOP category, our measures capture expenditure-share heterogeneity but not differences in prices paid, product quality, or within-category substitution.

Consumption-based inflation inequality requires both relative-price changes and heterogeneous expenditure shares. If all prices rose proportionally, fixed-basket inflation would be identical across households. Inequality emerges when relative-price movements interact with differences in household consumption baskets.

A related literature evaluates the fiscal response to the recent inflation surge. Using household microsimulation models, Pallotti et al. (2024) and Amores et al. (2025) show that fiscal interventions reduced welfare losses and inequality, although broad price measures were less targeted than income support. We instead reconstruct monthly no-policy price paths at the COICOP-component level for all 20 euro-area countries. This approach identifies which products drove the distributional effect of price-based policies: lower electricity and gas prices reduced the Quintile 1–Quintile 5 inflation gap, while fuel measures partly offset that reduction because higher-income households spend more on private transport.

This paper makes two contributions. First, we construct harmonized household-group price indices that aggregate to official HICP weights for all 20 euro-area countries. These indices measure HBS budget shares at both the group and household levels while holding item-level price changes common across households. They therefore capture variation in expenditure shares rather

than household-specific prices within narrowly defined products. Second, we show that price-based fiscal measures reduced inflation inequality in the euro area mainly by cushioning household-energy prices. The group-level indices document differences between income, age, and residence categories, while the household-level indices reveal dispersion within those broad categories.

The remainder of the paper is organized as follows. Section 1 describes the data and methodology. Section 2 examines developments in inflation inequality in the euro area. Section 3 presents simulations of the heterogeneous effects of unconventional fiscal policies. Section 4 turns to household-level inflation heterogeneity.

1 Data and Methodology

This section explains how the household-group inflation indicators are built from the same accounting logic as the Harmonised Index of Consumer Prices (HICP). We first describe the data sources and harmonization challenges that motivate the calibration of household-group weights to official HICP weights.

1.1 Constructing Household-Group Price Indices

Headline HICP inflation represents the price change faced by an average household basket. The paper computes the corresponding price index for household categories: income groups, age groups, and residence areas. Prices are common within each product category, as in the official HICP, but the expenditure weights differ across household groups.

This analysis is based on publicly available data, primarily the HICP constructed by national statistical institutes in collaboration with Eurostat. The HICP offers a standardized measure of inflation, ensuring comparability across Member States. Eurostat aggregates national HICPs. Each country's HICP is based on price changes for a fixed basket of goods and services, weighted according to household expenditure from country-specific sources, including national accounts, household budget surveys, and other national sources. The national indices are then aggregated into the euro area HICP using country-specific weights that reflect their share of total household consumption expenditure. ¹.

¹The calculation ensures comparability by adhering to Regulation (EU) 2016/792 and consistent data collection practices. The HICP is compiled according to the European classification of individual consumption by purpose (ECOICOP v2)

To ensure the HICP reflects recent consumption patterns, Eurostat updates its weighting structure annually. The updated weights are implemented with the January release of the HICP and remain fixed throughout the calendar year, which is the basis for the within-year Laspeyres aggregation. Let $\mathcal{J}_y$ denote the set of product categories with official HICP weights in year y . Let $p_{j,y,m}$ denote the price index of product category j in month m of year y , and let $p_{j,y,0}$ denote the price reference for the HICP weight year, corresponding to the previous December. The official within-year Laspeyres index is obtained by aggregating unchained product indices with the annual HICP product weights:

$$P_{y,m} = \sum_{j \in \mathcal{J}_y} \omega_{j,y}^{\text{HICP}} \cdot \frac{p_{j,y,m}}{p_{j,y,0}}. \quad (1)$$

The chained HICP index is then obtained by linking this within-year index to the previous December:

$$I_{y,m} = I_{y-1,12} \cdot P_{y,m}. \quad (2)$$

Figure 1 shows the developments across HICP components in the euro area since 2014. The HICP components show significant volatility in energy and fuel prices. The sharp rise starting around mid-2021 and peaking in 2022 reflects the post-COVID recovery, supply-chain disruptions, and geopolitical tensions. After the 2022 peaks, most components corrected visibly. Energy prices dropped sharply, while food prices and other components stabilized more gradually.

Consumption Data and Harmonization Challenges

The heterogeneity of consumption patterns among households is well-documented, but the accurate measurement of household-level consumption continues to present significant challenges. Estimating HICP inflation by household category requires Household Budget Surveys (HBS), which are national surveys on consumer expenditure.

The Household Budget Surveys cover a large sample (approximately 150,000 households in the euro area). Households are required to document their expenditures on consumer goods and services over a designated period, typically two weeks. These surveys capture the values of expenditures across COICOP categories. HBS data are generally collected every five years.² The most recent complete HBS wave generally refers to 2020. Data for this wave were collected between 2018 and 2022 in most EU Member States, with a few country-specific timing exceptions.

National statistical institutes in Italy and Spain also provide higher-frequency HBS data that can be used for country-specific extensions. Repeated HBS waves available for Spain suggest that,

²See [Accardo et al. \(2023\)](#), who estimate developments in consumption inequality between survey waves.

while behavioral changes over the course of a few years can be significant, point differences in the weights of the main consumption categories between low- and high-income households remain relatively stable (see Appendix A). Changes in overall consumption patterns may therefore have a limited effect on measured inflation inequality when consumption shares move in the same direction across income groups.

Figure 2: Consumption baskets by income quintiles in the euro area (in % of total expenditures)

Notes: Structure of consumption expenditure by income quintile. The euro-area aggregate combines the 2020 country-level HBS income-quintile expenditures for all 20 countries and is renormalized to 100 within each quintile. Italy uses baskets constructed from Istat HBS microdata; see Appendix C.

Sources: Eurostat HBS, Istat HBS microdata, and authors' calculations.

While HBS expenditure shares are observed only at low frequency, our weighting approach combines household-specific HBS expenditure structures with monthly HICP inflation rates. As a result, aggregate consumption patterns can evolve continuously over the business cycle, reflecting changes in the HICP. However, because cross-household expenditure heterogeneity is assumed to remain constant between two HBS waves, we use linear interpolation to smooth discrete changes between survey waves.

Figure 2 presents consumption baskets by income quintile. Lower-income households allocate a larger share of expenditure to essentials such as food and energy, increasing their exposure to price shocks in these categories. Housing and food account for a substantially larger share of expenditure among lower-income households. Energy-related expenditure for housing and

private transport is also much higher in rural areas than in cities, reflecting differences in heating needs and mobility constraints.

HICP and HBS are not directly harmonized. HICP item weights are updated every year and may rely on national accounts or other national sources, while HBS expenditure structures are observed at lower frequency. Depending on the level of data available, HICP and HBS are therefore merged at 3-digit COICOP in each country. In some cases, data published directly by national statistical institutes can be used instead of relying only on the Eurostat dataset. This approach is particularly valuable when the nationally published data provide greater granularity, recency, or frequency.³

The HBS contains many household characteristics that can be used to segment inflation exposure. In this paper, we focus on three dimensions: income, the age of the household reference person, and the area of residence.⁴ These variables make it possible to compare inflation experiences not only across the income distribution, but also across demographic groups and territorial contexts. Although imputed rent is outside the official HICP coverage, we retain it when constructing group-specific expenditure profiles; Appendix D explains this treatment and its implications for aggregation. Appendix Table D.1 also reports the sensitivity of the results to alternative rent mappings. For the euro area, the June 2021–June 2023 income-quintile inflation gap is 0.9 point under our baseline mapping of HBS actual and imputed rents (041+042) to HICP actual rents (041), compared with −0.5 point when only HBS actual rents are mapped to HICP 041 and 1.3 points when rents are excluded altogether. The treatment of rents therefore matters for the magnitude, and sometimes the sign, of measured inflation inequality, which supports retaining imputed rents in the group expenditure profiles rather than redistributing their expenditure share mechanically across non-housing items. This analysis uses all available waves of the HBS since 1999 and matches them with the closest corresponding HICP year. Country-specific extensions based on national HBS microdata are described in the appendices when harmonized Eurostat inputs are incomplete for the required household breakdowns.

These data constraints motivate the weighting methodology below. A simple use of HBS expenditure shares would generally not aggregate back to the official HICP, because the HBS all-

³The `inflationinequality` R package allows the use of national data at 4-digit COICOP.

⁴In recent HBS waves, Eurostat generally requests the Degree of Urbanisation (DEGURBA) variable, built from a common European methodology based on a 1 km² population grid. It classifies residence areas into cities (densely populated areas), towns and suburbs (intermediate density areas), and rural areas (thinly populated areas), using comparable thresholds across EU countries: urban centers of at least 50,000 inhabitants and 1,500 inhabitants per km², urban clusters of at least 5,000 inhabitants and 300 inhabitants per km², and all remaining areas.

household basket does not necessarily coincide with the annually updated HICP item weights. We therefore start from the official HICP product weights and use HBS only to distribute each product's expenditure across household groups. The Row and Column Adjustment Scaling (RAS) calibration preserves the relative HBS expenditure profiles while imposing the row and column margins required by the HICP construction.

Group-Specific Weights

Let $\omega_{j,y}^{\text{HICP}}$ denote the official annual HICP weight of product category j in weight year y . Let g denote a household group, such as an income quintile, an age group, or a residence-area group. Let y' denote the HBS wave matched to HICP weight year y . Let $E_{g,y'}^{\text{HBS}}$ and $E_{\text{all},y'}^{\text{HBS}}$ denote total HBS consumption expenditure by group g and by all households, respectively.

The weights $\omega_{j,g,y}$ are obtained from the RAS calibration. The algorithm preserves the relative HBS expenditure profiles while making the expenditure-weighted average of group baskets reproduce the official HICP item weights. Appendix D describes the RAS algorithm and compares it with the relative-expenditure normalization.

The calibrated aggregate expenditure matrix $M_{j,g,y}$ is required to satisfy the normalized HICP item-share margins. Let $s_{g,y}$ denote the share of total household consumption expenditure accounted for by group g in weight year y :

$$s_{g,y} = \frac{E_{g,y'}^{\text{HBS}}}{E_{\text{all},y'}^{\text{HBS}}}, \quad \sum_g s_{g,y} = 1. \quad (3)$$

Define the HICP weight normalized over the matched product set as

$$\bar{\omega}_{j,y}^{\text{HICP}} = \omega_{j,y}^{\text{HICP}} / \sum_{k \in \mathcal{J}_y} \omega_{k,y}^{\text{HICP}}.$$

The RAS calibration imposes:

$$\sum_{j \in \mathcal{J}_y} M_{j,g,y} = s_{g,y} \quad \text{for all } g, \quad \sum_g M_{j,g,y} = \bar{\omega}_{j,y}^{\text{HICP}} \quad \text{for all } j. \quad (4)$$

The product margin, $\sum_g M_{j,g,y} = \bar{\omega}_{j,y}^{\text{HICP}}$, ensures that the expenditure-weighted average of the group-specific weight assigned to each product reproduces the official HICP weight for that product. The group margin, $\sum_{j \in \mathcal{J}_y} M_{j,g,y}$, fixes the total expenditure mass of each household group, so that groups can retain different product structures while aggregating back to the published HICP basket. The final group-specific HICP weight is obtained by normalizing the calibrated matrix

within each group:

$$\omega_{j,g,y} = \frac{M_{j,g,y}}{s_{g,y}} = \frac{M_{j,g,y}}{\sum_{k \in \mathcal{J}_y} M_{k,g,y}}. \quad (5)$$

After aggregation, this calibration closely reproduces the official inflation rate (see Appendix D), and validation checks are reported in Appendix E.

The year of the HBS data y' and the HICP weight year y may therefore differ. To align the two sources, each HICP weight year y is matched with the most recent HBS wave available at or before that year. If no earlier HBS wave is available, the earliest HBS wave is used.

As a rule, HICP data are available on Eurostat at a level of detail corresponding to the 5-digit COICOP classification. However, certain product categories lack price data for specific periods. For instance, early-year price data for medical consultation services ("062") is often unavailable. To address these gaps, missing price indices are estimated based on the price developments of their parent product categories. In the case of "062", the price movements of the broader "health services" category ("06") are used to estimate the missing data.

Group-Level Consumer Price Indices

Let $p_{j,y,m}$ denote the Laspeyres price index of product category j in month m of year y . Let $p_{j,y,0}$ denote the price reference used for the HICP weight year y ; in the chained annual calculation this corresponds to the December price index of the previous year. The aggregation procedure is as follows: item indices are first unchained within the weight year, aggregated with annual expenditure weights, and then chained again.⁵ The group-specific within-year price index therefore combines unchained product indices with the group-specific weights defined above:

$$P_{g,y,m} = \sum_{j \in \mathcal{J}_y} \omega_{j,g,y} \cdot \frac{p_{j,y,m}}{p_{j,y,0}}. \quad (6)$$

The chained price index for household group g , denoted $I_{g,y,m}$, is then obtained by linking each within-year index to the previous December:

$$I_{g,y,m} = I_{g,y-1,12} \cdot P_{g,y,m}. \quad (7)$$

This notation keeps the two objects distinct: $\omega_{j,g,y}$ is the annual group-specific HICP weight of product j , while $I_{g,y,m}$ is the resulting monthly chained price index for group g .

⁵See Eurostat's `hicp` R package, which implements the Eurostat HICP aggregation.

2 Main Results

This section presents our main results. We focus on inflation inequality in the wake of the 2021–23 energy crisis and also document long-run inflation inequality in the euro area.

2.1 Inflation Inequality in the Euro Area

2.1.1 Short-Run Inflation Inequality

Figure 3 shows that the post-COVID inflation surge translated into moderate income-based inflation inequality in the euro area. Inflation rates for the first and fifth income quintiles remained close throughout the 2021–2023 period. Energy and food shocks raised headline inflation sharply, but their effects on the relative inflation exposure of low- and high-income households largely offset once national consumption structures and country-level price dynamics are combined across all 20 countries.

This pattern is broadly consistent with recent evidence from the ECB and [Claeys et al. \(2022\)](#), although small differences remain because of our weighting scheme and treatment of imputed rents.

Figure 3: Short-run inflation inequality in the euro area, by income quintile (year on year, in %)

Notes: This figure reports year-on-year inflation rates for the first and fifth income quintiles in the euro area from January 2020 to July 2026. The country series are aggregated using annual HICP country weights.

Sources: Eurostat HICP, HBS, authors' calculations

2.1.2 Inflation Inequality by Age and Residence Area

Figure 4 presents inflation rates by household category in the euro area, segmented by age and residence area. To ensure comparability with the 0.9-point cumulative Q1–Q5 gap, we compute all three gaps from chained price-index changes between June 2021 and June 2023, using indices based in 2020 and the same annual HICP country weights. Cumulative inflation was 15.2 percent for households aged 60 or over and 13.9 percent for households under 30, yielding an age gap of 1.3 points. It was 15.3 percent in rural areas and 14.3 percent in cities, yielding a rural–city gap of 1.0 point. The monthly annual inflation rates in the figure show that both gradients varied over time and temporarily narrowed or reversed as energy inflation receded.

The residence-area differentials reflect differences in the structure of energy demand. Rural households tend to spend a larger share of their budget on transport fuels and home energy, partly because commuting distances are longer and the set of available transport substitutes is more limited. This raises their exposure when energy prices accelerate, but also makes their measured inflation fall faster when those price pressures unwind.

Figure 4: Inflation by household categories in the euro area (year on year, in %)

Notes: This figure reports year-on-year inflation rates in the euro area by age (panel a) and residence area (panel b), January 2020 to July 2026. The cumulative gaps discussed in the text use the same endpoints as the income gap, June 2021 and June 2023, and are calculated as $100(P_{g,2023-06}/P_{g,2021-06} - 1)$ for each group before taking the difference. For age, cumulative inflation is 15.17 percent for households aged 60 or over and 13.90 percent for households under 30; the 60-or-over minus under-30 gap is therefore 1.27 points, rounded to 1.3. For residence, cumulative inflation is 15.27 percent in rural areas and 14.31 percent in cities; the rural-city gap is therefore 0.96 point, rounded to 1.0. All series use chained indices based in 2020 and annual HICP country weights.

Sources: Eurostat HICP, HBS, authors' calculations

2.1.3 Long-Run Inflation Inequality

Figure 5 shows a modest but persistent divergence between the first- and fifth-quintile price indices after 2008. The post-COVID episode produced the largest visible widening in the series since 2000.

Figure 5: Long-run inflation inequality in the euro area, by income quintile (index, 2000 = 100)

Notes: This figure shows monthly price indices for the first and fifth income quintiles in the euro area, January 2000 to July 2026. Indices are rebased to 2000 = 100.

Sources: Eurostat HICP, HBS, authors' calculations

This pattern contrasts with the larger long-run gaps documented for the United States in [Jaravel \(2024\)](#). Several methodological differences may account for the contrasting results. First, the euro-area indices reported here aggregate national indices and therefore average across countries whose price dynamics and fiscal responses can offset one another. Second, the euro-area calculation uses harmonized 3-digit COICOP categories, whereas the U.S. evidence exploits much finer product-level data. Aggregation within broad categories can conceal persistent differences in the prices paid by different income groups, which are captured in the U.S. data.

2.2 Heterogeneous Effects of the 2022–23 Energy Shock Across Countries

The 2021–23 inflation episode was marked by a large energy-price shock, especially in natural gas markets, following Russia's invasion of Ukraine. Although this shock was common to the euro area, its distributional effects differed across countries because energy mixes, import dependence, household consumption patterns, and fiscal responses were not uniform.

Table 1 documents this cross-country heterogeneity by reporting the cumulative June 2021–

June 2023 inflation gap between the first and fifth income quintiles. The Baltic countries and Ireland display large positive Quintile 1–Quintile 5 gaps, while several large economies show more compressed gaps.

The interaction between country-specific price dynamics, exposures, and fiscal policies and group-specific expenditure shares explains these differences. A price increase in a product category generates inflation inequality only to the extent that the affected category has different expenditure weights across household groups. Hence, similar income-quintile consumption profiles can still produce different inflation gaps when national energy prices, food prices, or fiscal cushioning measures evolve differently. Conversely, large aggregate shocks may generate limited inequality when price increases fall on categories with similar weights across quintiles or when policy measures dampen prices in essential energy components.

Table 1: Cumulative inflation gap between the first and fifth income quintiles, June 2021–June 2023

Country	Cumulative inflation	Q1 cumulative inflation	Q5 cumulative inflation	Inflation gap
Austria	17.2	17.5	17.1	0.4
Belgium	12.3	11.7	12.8	-1.1
Croatia	21.4	21.1	21.7	-0.6
Cyprus	12.0	12.7	12.0	0.7
Estonia	33.0	38.7	31.2	7.5
Finland	12.5	11.5	12.7	-1.2
France	12.2	12.3	12.1	0.2
Germany	15.6	16.5	15.2	1.3
Greece	14.7	15.1	14.5	0.6
Ireland	14.9	17.2	13.3	3.8
Italy	15.8	17.2	15.1	2.1
Latvia	28.9	36.0	26.5	9.5
Lithuania	30.4	33.6	29.0	4.6
Luxembourg	11.4	11.0	11.1	-0.2
Malta	12.7	13.8	12.2	1.6
Netherlands	16.9	17.7	16.5	1.2
Portugal	14.2	13.1	15.4	-2.3
Slovakia	25.4	26.7	24.0	2.7
Slovenia	18.1	19.9	17.5	2.4
Spain	11.8	11.8	11.7	0.1
Euro area	14.7	15.2	14.4	0.9

Notes. Cumulative inflation runs from June 2021 to June 2023. Gaps are the first group minus the second and are calculated from unrounded indices. The euro-area aggregate covers all 20 countries using annual HICP country weights. Entries are percentage points, rounded to one decimal. Sources: Eurostat, authors' calculations.

Housing energy and food raised the Quintile 1–Quintile 5 gap by 2.2 points between June 2021 and June 2023, but transport offset more than half of that increase (Table 2).

Table 2: Product-group contributions to euro-area cumulative income inflation gaps, June 2021–June 2023

Product group	Cumulative inflation	Q1 contribution	Q5 contribution	Inflation gap
Food and non-alcoholic beverages	4.3	5.2	4.5	0.7
Alcoholic beverage, tobacco and narcotics	0.5	0.7	0.4	0.2
Clothing and footwear	0.3	0.3	0.4	-0.1
Housing (rentals and repairs)	1.2	0.4	0.6	-0.2
Water, electricity, gas and other fuels	1.5	6.9	5.3	1.5
Transport	1.9	1.6	2.8	-1.2
Other	5.0	0.2	0.3	-0.1
Total	14.7	15.2	14.4	0.9

Notes. Contributions cumulate monthly changes from July 2021 to June 2023 and are rescaled to match the cumulative changes in Table 1. The gap is Q1 minus Q5. The euro-area aggregate covers all 20 countries using annual HICP country weights. Entries are percentage points. Sources: Eurostat, authors' calculations.

2.3 Direct and Indirect Exposure to Energy Price Shocks

This section examines whether this exposure arose primarily from households' direct purchases of energy or from cost increases transmitted through production networks. We combine an input–output model with group-specific expenditure weights to decompose the simulated inflation effects into direct and indirect components.

Let $\mathbf{A}$ denote the matrix of intermediate-input coefficients in the euro area and let $\mathbf{s}$ be the sectoral price shocks. The Leontief price response is

$$\Delta \mathbf{p} = \underbrace{\mathbf{s}}_{\text{direct}} + \underbrace{\left[(\mathbf{I} - \mathbf{A}^T)^{-1} - \mathbf{I} \right] \mathbf{s}}_{\text{indirect}}. \quad (8)$$

The first term is the price change in the sectors initially shocked. The second term captures domestic and cross-country propagation through intermediate inputs. Let $\mathbf{M}$ denote the NACE–COICOP bridge from Cai and Vandyck (2020), normalized within each consumption category, and let $\mathbf{w}_g$ denote the expenditure weights of household group g . The corresponding direct, indirect, and total household-price effects are

$$\Delta \pi_g^{\text{direct}} = \mathbf{w}_g^T \mathbf{M} \mathbf{s}, \quad (9)$$

$$\Delta \pi_g^{\text{indirect}} = \mathbf{w}_g^T \mathbf{M} \left[(\mathbf{I} - \mathbf{A}^T)^{-1} - \mathbf{I} \right] \mathbf{s}, \quad (10)$$

$$\Delta \pi_g = \Delta \pi_g^{\text{direct}} + \Delta \pi_g^{\text{indirect}}. \quad (11)$$

Distributional exposure is the difference between group effects. For income quintiles, for example, $\Delta\pi_{Q1-Q5} = \Delta\pi_{Q1} - \Delta\pi_{Q5}$, with the same decomposition into direct and indirect components.

The simulation imposes a 27 percent production-price shock in every euro-area country on oil, refined petroleum and electricity, gas. The initial shock s defines the direct effect; the remaining response generated by the price system captures domestic and cross-border cost propagation through intermediate inputs. We map the production price changes to consumption products and aggregate them using official HICP country and product weights for the average basket and expenditure weights for Q1 and Q5.

The mapping assumes complete and immediate pass-through from basic-price changes to the corresponding HICP consumption categories. The bridge aligns classifications but does not separately model retail and transport margins, taxes, subsidies, imported final goods, or incomplete pass-through. The resulting effects should therefore be read as exposure under a common accounting assumption, not as causal estimates of consumer-price responses.

Table 3: Effect of a 27% energy-sector shock by product group, euro area, 2021–2023

Product group	Average effect	Q1 effect	Q5 effect	Inflation gap	Direct gap	Indirect gap
Food and non-alcoholic beverages	0.4	0.5	0.4	0.2	0.0	0.2
Alcoholic beverage, tobacco and narcotics	0.1	0.1	0.1	0.0	0.0	0.0
Clothing and footwear	0.1	0.1	0.1	0.0	0.0	0.0
Housing (rentals and repairs)	0.2	0.2	0.2	0.0	0.0	0.0
Water, electricity, gas and other fuels	1.3	3.6	2.0	1.6	1.1	0.5
Transport	1.6	1.2	1.8	-0.6	-0.4	-0.2
Other	0.7	0.6	0.7	-0.1	0.0	-0.1
Total	4.4	6.2	5.3	1.0	0.7	0.3

Sources: Eurostat HICP, HBS, FIGARO, authors' calculations.

Notes. Entries are percentage-point effects of a uniform 27 percent energy-price shock in every euro-area country.

Product groups follow the mapping used in Table 2. The average effect uses official HICP product and country weights; Q1 and Q5 use group-specific RAS expenditure weights. When an HBS weight is available only for a broader consumption category than the input–consumption bridge, bridge shares are aggregated using official HICP weights.

Direct and indirect gaps sum to the Q1–Q5 inflation gap before rounding. Indirect effects include domestic and cross-country input-output propagation through FIGARO. Totals and gaps are calculated before rounding and may differ slightly from sums or differences of the displayed components. Q1–Q5 denotes the first income quintile minus the fifth.

Table 3 shows that the shock raises average euro-area inflation by 4.4 percentage points. Transport and household energy account for 1.6 and 1.3 points, respectively, while other products and food contribute 0.7 and 0.4 point. These product contributions combine the sectoral price response

from the FIGARO network with each product’s weight in the relevant household basket.

The distributional effect is concentrated in household energy. The shock raises Q1 inflation through water, electricity, gas, and other fuels by 3.6 points, compared with 2.0 points for Q5, adding 1.6 points to the Q1–Q5 gap. Higher-income households devote a larger share of their consumption basket to transport and are therefore more exposed to refined-petroleum price shocks. This channel lowers the Q1–Q5 inflation gap by 0.6 point, but does not offset the household-energy channel. The total simulated gap is 1.0 point, of which 0.7 point reflects direct exposure and 0.3 point indirect production-network propagation. Its proximity to the observed 0.9-point gap in Table 2 should not be interpreted as a model fit: the simulation applies a uniform shock with complete pass-through, whereas observed consumer prices also reflect country-specific taxes, subsidies, regulated tariffs, and other price shocks.

The energy shock widens the income gap mainly because lower-income households devote more of their budgets to electricity, gas, and other household fuels. Production networks reinforce this direct exposure, but account for less than one third of the simulated gap. Price caps, tariff shields, and tax or charge reductions can therefore reduce inflation inequality most strongly when they lower the retail prices of household energy, the component that generates the largest direct gap.

3 Effects of Household Fiscal Policies on Inflation Inequality

This section evaluates the distributional effects of unconventional fiscal policies implemented during the 2021–2023 energy crisis that directly changed consumer prices faced by households, including electricity and gas price caps and shields, VAT and energy-tax reductions, cuts in regulated charges, and fuel rebates.

3.1 Constructing No-Policy Counterfactual Price Indices

In response to the energy crisis, euro area governments introduced a broad array of measures to mitigate household exposure to rising energy costs (Arregui et al., 2022, Dao et al., 2023, García-Miralles, 2023, Levell et al., 2026). These included both direct income support, such as cash transfers to vulnerable groups, and price-based interventions, including temporary VAT reductions and price ceilings on gas, electricity, and fuel. Despite this variety, governments in the euro area relied predominantly on measures that directly reduced consumer energy prices rather than on narrowly

targeted income support. We use [Sgaravatti et al. \(2021\)](#)'s dataset ⁶ to identify the price-relevant measures and dates. We then construct counterfactual HICP component paths without those interventions. In the Bruegel inventory for the 20 euro-area countries, measures acting directly on prices accounted for EUR 266.9 billion out of EUR 400.6 billion in total household support, or 66.6 percent. Of this price-based support, EUR 234.1 billion was delivered through untargeted measures and EUR 32.8 billion through measures targeted at vulnerable households.

The measures differed substantially across euro area countries. Some governments relied primarily on regulated retail-price caps or tariff shields, while others used VAT and excise-tax reductions, fuel rebates, system-charge reductions, or calibrated block-tariff schemes. Table [B.1](#) in the appendix reports the euro-area inventory and indicates which measures are directly simulated in our price counterfactuals. We construct counterfactual price indices for the countries and policy instruments for which the necessary statutory, price, and unit-conversion information is available; Appendix [B](#) reports the corresponding country-level counterfactual series.

To quantify the effect of these fiscal measures on inflation inequality, we construct a counterfactual scenario in which no such price-based policies were enacted. Specifically, we compare the actual trajectory of policy-inclusive retail prices with estimated no-policy price paths for the affected products. This comparison allows us to isolate the extent to which fiscal policy contributed to reducing inflationary pressures and their unequal distribution across households. These measures are temporary support instruments rather than substitutes for monetary policy: their direct effect operates through administered prices, tax-inclusive prices, retail price ceilings, or unit rebates, and is therefore concentrated in the product categories to which they apply.

We distinguish three cases according to the information available. Measures with observed no-policy tariffs, statutory tax rates, or statutory unit rebates require no calibration: their affected component, policy window, and monthly price wedge come directly from the underlying sources, and we apply the observed or statutory ratio with unit intensity. Calibration enters only when the inventory identifies an intervention but lacks the monthly tariff path, unit price, or coverage weights needed for a direct reconstruction. In these cases, we choose one measure-specific intensity parameter so that the geometric mean of the implied monthly no-policy price ratios over the active policy months equals an audited aggregate-equivalent target ratio. First, for regulated-price shields, price caps, and administered tariffs, we use an observed no-policy reference tariff when available. Otherwise, we calibrate an aggregate-equivalent price wedge. Second, for VAT and excise changes, we back out the reduced tax-inclusive price and reapply the normal rate; a coverage

⁶<https://www.bruegel.org/dataset/national-policies-shield-consumers-rising-energy-prices>

and pass-through parameter is needed only when full statutory coverage cannot be established. Third, for unit subsidies and fuel rebates, we add the statutory absolute price wedge back to the observed monthly price path; when no retail unit-price series is available, the wedge is calibrated in HICP component-index units. Evidence from [Drolsbach et al. \(2023\)](#) suggests that temporary fuel-tax reductions and discounts were largely passed through to consumer prices in 2022 in several euro area countries, although pass-through varied over time and by fuel type. This supports treating these measures as retail-price wedges in the counterfactual construction.

Counterfactual price indices are constructed at COICOP digit 3 by replacing the observed HICP with a no-policy component-index. Let $P_{j,t}$ denote the observed HICP component index for product j in month t , and let $\tilde{P}_{j,t}$ denote the corresponding counterfactual index. For each simulated measure, we recover a counterfactual retail price $\tilde{p}_{j,t}$ and apply the implied price ratio to the observed component index:

$$\tilde{P}_{j,t} = P_{j,t} \frac{\tilde{p}_{j,t}}{p_{j,t}}. \quad (12)$$

VAT and Excise-Tax Reductions. For VAT or excise-tax reductions, the observed retail price includes the reduced policy tax rate. Following the standard tax-inclusive price logic used to assess the inflation effects of VAT changes ([Gautier and Lalliard, 2013](#)), the no-policy price is obtained by backing out the reduced tax-inclusive price and reapplying the normal tax rate:

$$\tilde{p}_{j,t} = p_{j,t} \frac{1 + \tau_{j,t}^0}{1 + \tau_{j,t}^1}, \quad (13)$$

where $\tau_{j,t}^1$ is the policy tax rate and $\tau_{j,t}^0$ is the no-policy tax rate.

Administered Prices. For regulated or administered-price measures, such as electricity or gas tariff shields and retail price caps, the counterfactual price is taken from a no-policy reference path:

$$\tilde{p}_{j,t} = p_{j,t}^{\text{ref}}. \quad (14)$$

When the observed tariff and the no-policy reference tariff are both available, the no-policy retail price is obtained by rescaling the observed price. If $T_{j,t}^{\text{obs}}$ denotes the regulated tariff actually applied and $T_{j,t}^{\text{ref}}$ the tariff that would have applied without the intervention, then:

$$p_{j,t}^{\text{ref}} = p_{j,t} \frac{T_{j,t}^{\text{ref}}}{T_{j,t}^{\text{obs}}}. \quad (15)$$

Subsidies and Rebates. For unit subsidies, fuel rebates, or per-kWh support schemes, the observed price is lower than the no-policy price by the statutory support amount. The counterfactual price is obtained by adding the support amount $s_{j,t}$ back to the observed unit price:

$$\tilde{p}_{j,t} = p_{j,t} + s_{j,t}. \quad (16)$$

For transport-fuel rebates, $s_{j,t}$ is recovered from the statutory pump discount, expressed in euros per litre, and applied to a monthly retail-fuel price consistent with the HICP transport-fuel component. Following [Bonnet et al. \(2025\)](#), we refer to these interventions as pump-price rebates or subsidies because they reduced the tax-inclusive price paid by consumers, although their technical implementation sometimes operated through fuel excise taxation rather than through a direct transfer to households. The no-rebate fuel index is obtained by rescaling the observed HICP transport-fuel component:

$$\tilde{P}_{j,t} = P_{j,t} \frac{p_{j,t}^M + s_{j,t}}{p_{j,t}^M}.$$

More generally, when the Bruegel dataset identifies a subsidy but does not supply a monthly unit price, we set $s_{k,t} = \delta_k \bar{P}_j$ in component-index units. This yields the time-varying ratio $1 + \delta_k \bar{P}_j / P_{j,t}$. The single parameter δ_k is calibrated.

For a small set of price-relevant interventions, the policy inventories identify the measure but do not provide the monthly no-policy tariff schedule, tariff-block utilization, or eligible-household weights needed for a direct statutory reconstruction. We therefore add these cases as separate calibrated layers, identified from [Sgaravatti et al. \(2021\)](#) and [Arregui et al. \(2022\)](#), rather than merging them with the VAT or unit-subsidy calculations. This applies to block-tariff or price-cap schemes in Germany, the Netherlands, Cyprus, Ireland, Italy, and Slovenia, and to Belgium’s extension of the social energy tariff and basic energy package. The calibrated ratios are applied only to the relevant COICOP energy components and policy months, and the corresponding assumption tables are reported with the counterfactual outputs. These layers should be interpreted as aggregate-equivalent price effects, not as statutory tariff reconstructions.

We therefore distinguish the information basis of the counterfactuals. The first layer uses statutory tax rates, unit rebates, or observed reference tariffs; the second uses aggregate-equivalent calibrated wedges when a statutory reconstruction is incomplete.

The counterfactual component indices are then used in the same household-group inflation procedure as the observed indices. Replacing the observed component indices $P_{j,t}$ with $\tilde{P}_{j,t}$ yields a chained counterfactual group index $\tilde{I}_{g,t}$. The counterfactual inflation rate for group g is then computed as the year-on-year growth rate of this index.

3.2 Effect of Household Price Policies on Average Inflation

We aggregate the country-level policy counterfactuals across all 20 countries using Eurostat HICP country weights.

Figure 6 shows that the simulated household price policies compressed euro-area inflation during the energy crisis. The gap between observed all-items HICP inflation for the euro area and the corresponding no-policy counterfactual is largest around the peak of the 2022–23 energy shock, when VAT reductions, fuel rebates, price shields and regulated-price caps were simultaneously active across countries.

Figure 6: Household price policies: observed and no-policy euro-area inflation (year on year, in %)

Notes: The no-policy series removes fiscal interventions that directly affected consumer prices. The figure reports year-on-year inflation for all 20 euro-area countries, aggregated with annual HICP country weights, from January 2021 to July 2026. Cumulative inflation is measured between June 2021 and June 2023; the policy effect is defined as observed minus no-policy inflation.

Sources: Eurostat HICP; Bruegel energy-policy dataset; authors' calculations.

3.3 Effect of Household Price Policies on Inflation Inequality

Table 4 reports the fiscal cost of household price policies and cumulative no-policy inflation, together with the corresponding income-quintile indices and inflation gap. The fiscal costs provide

context for the scale of the interventions⁷.

Without the simulated price-based fiscal interventions, inflation for the first income quintile would have risen further above inflation for the fifth quintile. Figure 7 shows the corresponding monthly no-policy paths.

Figure 7: Household price policies: no-policy euro-area inflation by income quintile (year on year, in %)

Notes: The figure reports year-on-year inflation rates in the absence of household price policies for the first and fifth income quintiles, from January 2021 to July 2026. Income transfers and firm-only measures are outside the counterfactual. All 20 countries, including Italy and Spain, use RAS expenditure weights and are aggregated using annual HICP country weights.

Sources: Eurostat HICP and country weights; household budget surveys; Bruegel energy-policy dataset; authors' calculations.

⁷These fiscal costs are not inputs into the price-index counterfactual and do not measure the monetary benefit received by each household group

Table 4: Household price policies: fiscal cost and no-policy inflation in the 20 euro-area countries, June 2021–June 2023

Country	Fiscal policies on prices (EUR bn)	Counterfactual inflation	Effect of price policies on average inflation	Q1 counterfactual inflation	Q5 counterfactual inflation	Counterfactual inflation gap	Effect of price policies on inflation inequality
Austria	3.8	17.7	-0.5	19.3	18.2	1.1	-0.7
Belgium	5.3	12.8	-0.5	13.5	14.0	-0.5	-0.6

Portugal	5.6	14.8	-0.6	15.5	17.0	-1.5	-0.8
Slovakia	2.3	26.9	-1.6	33.5	27.8	5.7	-3.0
Slovenia	0.1	18.4	-0.3	21.1	18.1	2.9	-0.6
Spain	23.1	12.5	-0.7	14.6	13.5	1.1	-1.0
Euro area	266.9	15.4	-0.7	18.2	16.2	2.0	-1.2

Notes. The no-policy counterfactual replaces prices affected by household price policies and retains other observed prices. The inflation gap is Q1 minus Q5. Policy effects are observed minus no-policy values; negative values indicate a reduction in inflation or in the gap. Fiscal costs cover household price policies, exclude income transfers and firm-only measures, and are reported in EUR billions. The euro-area aggregate covers all 20 countries using annual HICP country weights. Inflation entries are percentage points. Sources: Eurostat, national statistical institutes, authors' calculations.

Table 5 reproduces the product-group decomposition of Table 2 using the no-policy counterfactual price paths. It reports each product group's contribution to counterfactual cumulative inflation and to the Quintile 1–Quintile 5 gap, together with the estimated effect of household price policies on inflation inequality.

Table 5: Household price policies: product-group contributions to no-policy inflation inequality in the 20-country euro area, June 2021–June 2023

Product group	Counterfactual inflation	Q1 counterfactual contribution	Q5 counterfactual contribution	Counterfactual inflation gap	Effect of price policies on inflation inequality
Food and non-alcoholic beverages	4.5	5.4	4.6	0.8	-0.1
Alcoholic beverage, tobacco and narcotics	0.5	0.7	0.4	0.2	0.0
Clothing and footwear	0.3	0.3	0.4	-0.2	0.0
Housing (rentals and repairs)	0.5	0.4	0.6	-0.2	0.0
Water, electricity, gas and other fuels	6.9	9.4	6.5	2.9	-1.4
Transport	2.4	1.8	3.2	-1.4	0.2
Other	0.3	0.2	0.4	-0.2	0.0
Total	15.4	18.2	16.2	2.0	-1.2

Notes. The no-policy counterfactual replaces prices affected by household price policies and retains other observed prices. The gap is Q1 minus Q5. Policy effects are observed minus no-policy values; negative values indicate that policies reduced the gap. The euro-area aggregate covers all 20 countries using annual HICP country weights. Entries are percentage-point contributions. Sources: Eurostat, national statistical institutes, authors' calculations.

For the euro area, cumulative inflation from the total no-policy HICP index is 15.4 percent. Counterfactual cumulative inflation is 18.2 percent for Quintile 1 and 16.2 percent for Quintile 5, compared with observed values of 15.2 and 14.4 percent reported in Table 1. The observed Quintile 1–Quintile 5 gap is therefore 0.9 point, compared with 2.0 points without the simulated measures. Using unrounded indices, the resulting policy effect is -1.2 points. For comparison, the U.S. distributional CPIs of [Jaravel \(2024\)](#) imply cumulative inflation of 13.0 percent for the first income quintile and 13.5 percent for the fifth between May 2020 and May 2022, a Q1–Q5 gap of -0.5 point. The U.S. profile is inverse U-shaped—inflation reaches 14.7 percent for the middle class—rather than monotonically declining with income. The sign and size of inflation inequality therefore depend on both the composition of the price shock and the policies affecting the most exposed categories.

The product decomposition shows the mechanism behind the -1.2 -point effect. Household price policies reduce the contribution of electricity and gas to the Q1–Q5 gap by 1.4 points. Their effect through transport instead increases the gap by 0.2 point, because fuel-price measures also benefit the transport-intensive baskets of higher-income households. Effects through the remaining product groups are close to zero. This pattern mirrors the input–output simulation: both exercises identify household energy as the dominant distributional channel, while transport partly offsets it. The fiscal measures thus dampen the same direct exposure that generates most of the simulated energy-shock gap; they do less to undo the smaller component transmitted indirectly

through production networks.

The distributional effects are heterogeneous across countries. Among the countries included in the euro-area aggregate, the largest reductions in the Quintile 1–Quintile 5 gap are estimated for Slovakia (−3.0 points), France (−2.6), Greece (−1.4), Lithuania and the Netherlands (−1.1 each), and Spain (−1.0). Italy has a policy effect of −0.3 point. Estimates close to zero arise either where no policy layer from Appendix B enters the country row or where temporary counterfactual price wedges leave little difference in the June 2021–June 2023 endpoint comparison. Figure 6 and the monthly developments in Appendix B complement this cumulative comparison by showing when the measures affected inflation.

France combines a reported budget of EUR 80.5 billion with a 2.6-point reduction in the Q1–Q5 inflation gap, whereas Slovakia combines EUR 2.3 billion with a 3.0-point reduction. These figures refer to economies of different sizes, policy coverage, energy systems, and initial price exposures. The inflation-gap effect is measured in percentage points, not as a monetary gain, and it cannot be divided meaningfully by expenditure in euros. A cost-effectiveness analysis would need household-level policy eligibility, quantities consumed, tax and transfer rules, and counterfactual expenditures to calculate the fiscal cost and purchasing-power benefit for each household in a common monetary unit.

4 Household-Level Inflation

This section moves from inflation indices for broad household groups to estimates constructed from individual household records. We use the consumption basket reported by each household in the HBS microdata which we combine with monthly HICP price indices. This approach shows the dispersion within groups and allows us to examine whether observable household characteristics are systematically associated with inflation exposure.

4.1 Calculating Household Inflation Rates

We apply fixed-basket Laspeyres at the household level, holding each household’s 2020 HBS basket fixed when calculating inflation for 2021–2023. Let $e_{i,j,2020}^{\text{HBS}}$ denote household i ’s expenditure on COICOP item j in the 2020 HBS wave, and let $a_{i,2020}$ denote its survey weight. The household expenditure share is

$$\omega_{j,i,2020}^{\text{HBS}} = \frac{a_{i,2020} e_{i,j,2020}^{\text{HBS}}}{\sum_{k \in \mathcal{J}_{i,2020}} a_{i,2020} e_{i,k,2020}^{\text{HBS}}} = \frac{e_{i,j,2020}^{\text{HBS}}}{\sum_{k \in \mathcal{J}_{i,2020}} e_{i,k,2020}^{\text{HBS}}} \quad (17)$$

using the same convention as the group-specific weights $\omega_{j,g,y}$ defined above. Since the same survey weight applies to all items within a household, it cancels out in the within-household basket; it is then used to weight households when constructing cross-household distributions and summary statistics. For household i , the within-year price index in month m of year y is

$$P_{i,y,m} = \sum_{j \in \mathcal{J}_{i,2020,y}} \omega_{j,i,2020}^{\text{HBS}} \frac{p_{j,y,m}}{p_{j,y,0}}, \quad (18)$$

where $\mathcal{J}_{i,2020,y}$ is the set of household expenditure items observed in the 2020 HBS wave that can be matched to HICP prices in year y . Households are therefore treated as elementary household groups: the within-year Laspeyres changes are chain-linked at the household level, and year-on-year monthly inflation rates $\pi_{i,y,m}$ are computed from the resulting chained household price index.

For each household i in country c and calendar year y , average annual inflation is the arithmetic mean of the 12 monthly year-on-year inflation rates. If $I_{ic,y,m}$ is the chained household price index, then

$$\pi_{ic,y,m} = 100 \left(\frac{I_{ic,y,m}}{I_{ic,y-1,m}} - 1 \right), \quad \bar{\pi}_{ic,y} = \frac{1}{12} \sum_{m=1}^{12} \pi_{ic,y,m}. \quad (19)$$

This annual average is the inflation measure used in the household-level regressions and in the inflation-burden calculation below.

Figure 8 shows the dispersion of these household-level inflation rates across the euro-area microdata sample in 2021, 2022, and 2023.

Figure 8: Distribution of household-level inflation in the euro area, 2021–2023 (in % of households)

Notes: Histograms report the survey-weighted percentage of households by annual inflation interval, calculated from fixed 2020 household consumption baskets. The displayed range excludes the outer 0.1 percent of the pooled weighted distribution. The sample covers 19 euro-area countries; Portugal is excluded because no household basket can be matched to the annual HICP series.

Sources: Eurostat HICP and HBS microdata; authors' calculations.

4.2 Inflation Burden

Our indicators measure differences in inflation exposure across household groups, but they do not directly express the cost of inflation relative to household resources. We therefore construct the burden from HBS microdata rather than combining group-level inflation with an external aggregate consumption-to-income ratio. For household i in country c , let X_{ic} denote total consumption expenditure, Y_{ic} net household income, and $\bar{\pi}_{ic,y}$ the household's average annual inflation rate in year y , computed from its own COICOP expenditure shares and the corresponding national HICP price changes. The raw household-level burden is

$$b_{ic,y}^{\text{raw}} = \bar{\pi}_{ic,y} \frac{X_{ic}}{Y_{ic}}, \quad (20)$$

where $\bar{\pi}_{ic,y}$ is measured in percent, so $b_{ic,y}^{\text{raw}}$ is measured in points of net income. Thus, the indicator allows both individual inflation exposure and the consumption-to-income ratio to vary across households.

Very small reported incomes can generate mechanically extreme expenditure-to-income ratios. We therefore winsorize $100X_{ic}/Y_{ic}$ at the survey-weighted 99th percentile within each country, while retaining the underlying household inflation rate. Denoting the resulting ratio by $\tilde{\kappa}_{ic}$, the burden used in the estimates and its aggregation for national income quintile q are

$$b_{ic,y} = \tilde{\pi}_{ic,y} \frac{\tilde{\kappa}_{ic}}{100}, \quad B_{q,y} = \frac{\sum_c \sum_{i \in q(c)} a_{ic} b_{ic,y}}{\sum_c \sum_{i \in q(c)} a_{ic}}, \quad (21)$$

where a_{ic} is the HBS survey weight and $q(c)$ indicates that equivalized-income quintiles are defined separately within each country before households are pooled. The survey weights expand the microdata to national household populations and therefore determine the euro-area aggregation. The 2020 HBS basket, income, and expenditure observations are held fixed, while household-specific inflation is calculated for 2021–2023. For each household-year, the inflation rate is computed over the expenditure categories matched to available HICP items and the matched shares are renormalized to one. We impose no minimum matched-expenditure threshold.

Higher-income households also generally have greater capacity to absorb a price shock by reducing discretionary expenditure or substituting toward cheaper varieties. Appendix Figure A.2 documents the corresponding difference in basket composition.

Figure 9 reports the weighted household-level burden. The first quintile faces a substantially larger burden in every year: 3.1 percent of net income in 2021, 10.2 percent in 2022, and 7.4 percent in 2023, compared with 2.0, 5.7, and 4.1 percent for the fifth quintile. The Q1–Q5 burden gap therefore widened from 1.1 points in 2021 to 4.5 points at the peak of the energy-price shock in 2022, before narrowing to 3.3 points in 2023.

Figure 9: Household-level inflation burden in the euro area, by income quintile (in % of net income)

Notes: The burden is computed for each household as its annual basket-specific inflation rate multiplied by its consumption-to-net-income ratio. Ratios are winsorized at the survey-weighted national 99th percentile; income quintiles are defined within countries. Estimates use the 2020 HBS microdata and annual inflation for 2021–2023. Italy is excluded because the harmonized micro-income input is unavailable. Portugal is absent because no household basket can be matched to the annual HICP series. The resulting sample covers 18 euro-area countries.

Sources: Eurostat HICP and HBS microdata; authors' calculations.

4.3 Household Characteristics and Inflation Exposure

We pool individual household records from the euro area to examine whether differences in consumption baskets translate into systematic differences in inflation exposure. We examine how income quintile, age, household size, and degree of urbanization are associated with household-specific inflation.

Table 6 reports separate regressions for 2021, 2022, and 2023, with country fixed effects. Table 7 pools the three years and includes both country and year fixed effects. Hence, the coefficients capture conditional differences between households within countries, net of the included characteristics and common country effects; the pooled estimates additionally net out the large common changes in inflation across years. They should be interpreted as descriptive conditional associations, not as causal effects.

Table 6: Household-level inflation regressions by year, euro-area sample

Notes: The dependent variable is mean annual household inflation, in percent. Regressions are estimated separately by inflation year using household survey weights and include country fixed effects. The omitted categories are income quintile 1 and rural areas. The estimation sample covers 18 euro-area countries; Italy lacks usable harmonized household income and Portugal has no household basket that can be matched to the annual HICP series. Standard errors clustered by country are reported in parentheses.

Sources: Household Budget Survey microdata; Eurostat HICP; authors' calculations.

All three regressions use household records from the same 2020 HBS wave and impose no minimum matched-expenditure threshold. Annual inflation can nevertheless be calculated only when at least one category in a household's basket matches an HICP item with sufficient monthly

price coverage. After removing the matching threshold, the estimation sample contains 152,438 observations in 2021 and 152,440 in both 2022 and 2023. Only two regression observations therefore lack sufficient price matches in 2021. The effective estimation sample is otherwise constant across years.

Notes: The dependent variable is mean annual household inflation, in percent. The regression uses household survey weights and includes country and inflation-year fixed effects. The omitted categories are income quintile 1 and rural areas. The estimation sample covers 18 euro-area countries; Italy lacks usable harmonized household income and Portugal has no household basket that can be matched to the annual HICP series. Standard errors clustered by country are reported in parentheses.

Sources: Household Budget Survey microdata; Eurostat HICP; authors' calculations.

The income-quintile coefficients change sign over time. Relative to the first quintile, households in the upper quintiles experienced higher inflation in 2021: the coefficients rise from 0.11 point for the second quintile to 0.31 point for the fifth. In 2022, all four coefficients are negative

and statistically significant, ranging from -0.63 to -0.85 points, with the largest difference for the fifth quintile. The coefficients remain negative in 2023, between -0.15 and -0.22 points; three of the four are statistically different from zero at the 10 percent level. In the pooled specification, they range from -0.21 to -0.26 point. The second-quintile coefficient is significant at 5 percent and the fifth-quintile coefficient at 10 percent, whereas the middle-quintile coefficients are not statistically different from zero. Thus, higher-income households had slightly higher inflation in 2021 but lower inflation during 2022–23; the results do not support a stable linear relationship between income rank and household inflation over the full period.

Age differences are largest during the energy-price shock. Relative to households whose reference person is aged 60 or over, households under 30 experienced 2.01 points lower inflation in 2022 and 0.67 point lower inflation in 2023. The corresponding differences for households aged 30–44 were -1.39 and -0.57 points, and those for households aged 45–59 were -0.89 and -0.30 points. The pooled coefficients preserve this age gradient, ranging from -0.40 point for ages 45–59 to -0.95 point for households under 30.

Household size is also associated with inflation exposure, but its sign varies across years. Each additional household member is associated with 0.02 point higher inflation in 2021, 0.07 point lower inflation in 2022, and 0.12 point higher inflation in 2023. The pooled estimate is positive but small, at 0.02 point. This instability suggests that household size mainly proxies for differences in baskets whose inflation sensitivity depends on the composition of the shock, rather than a persistent exposure gradient.

Residence differences are concentrated in 2021–22. Conditional on the other covariates and country effects, inflation in 2022 is estimated to be 0.74 point lower in intermediate-density areas and 1.43 points lower in densely populated areas than in rural areas. In 2023, the differences narrow to 0.02 point higher inflation in intermediate areas and 0.04 point lower inflation in densely populated areas. The pooled estimates are respectively -0.33 and -0.69 point. The large 2022 gaps are consistent with rural households allocating larger shares to home energy and private transport, the categories most exposed to the energy-price shock.

5 Conclusion

This paper constructs indicators to measure inflation inequalities across socio-demographic groups in the euro area. Between June 2021 and June 2023, the cumulative Quintile 1–Quintile 5 gap was 0.9 point, compared with 1.3 points between households aged 60 or over and those under 30,

and 1.0 point between rural and urban households. These differentials are concentrated around the energy-price surge and narrowed as energy inflation receded. Inflation inequalities remain limited in a low-inflation environment.

Similar average inflation rates nevertheless imposed sharply different burdens. In 2022, inflation absorbed 10.2 percent of net income for households in the first income quintile, compared with 5.7 percent for those in the fifth. Household characteristics also mattered. Age and residence show the largest conditional differences during the energy shock: the rural–urban gradient is pronounced in 2021–22 but vanishes in 2023, while the age gradient persists through 2023. Income and household size display less stable relationships across years. VAT reductions, fuel rebates, and energy price shields lowered average cumulative inflation by 0.7 point and reduced the aggregate Quintile 1–Quintile 5 gap by 1.2 points in the no-policy comparison.

In the policy counterfactual, lower household-energy prices reduce the Q1–Q5 gap by 1.4 points, while lower transport prices increase it by 0.2 point. Unconventional fiscal measures were therefore distributionally effective mainly because they targeted the retail energy prices to which lower-income households were directly exposed. These measures had little effect on price increases transmitted through firms’ input costs.

In the euro area, price-based fiscal measures temporarily cushioned the distributional effects of the 2021–2023 inflation surge, while the subsequent disinflation unfolded alongside monetary tightening aimed at restoring aggregate price stability. Recent fiscal measures reduced inflation inequality in the euro area, while assessing the distributional effects of monetary policy lies beyond the scope of this paper and requires a heterogeneous-agent model.

Income alone does not identify vulnerable households: residence and age also capture differences in heating technology, mobility constraints, and the ability to substitute between products. More granular transaction and expenditure data would allow future work to measure substitution within product categories.

An extension of this article would combine household-specific price indices with harmonized euro-area household balance-sheet surveys to assess the heterogeneous effects of inflation on household wealth, particularly across debtors and creditors and across households with different asset and liability compositions.

A Additional Figures on the Household Budget Surveys

Figure A.1: Main COICOP expenditure weights by income quintile, Spain (in % of total expenditure)

Notes: The figure reports the share of each main COICOP category in total household expenditure for the first and fifth equivalized-income quintiles. Quintiles are computed separately by year using household weights.

Sources: INE Encuesta de Presupuestos Familiares public-use microdata; authors' calculations.

Figure A.2: Essential and discretionary expenditures by income quintile, euro area (in % of total expenditure)

Notes: The figure partitions COICOP expenditure shares into essential expenditures and discretionary/transport expenditures. The euro-area aggregate is computed as the unweighted average of available country-level HBS expenditure shares.

Sources: Eurostat HBS 2015; authors' calculations.

B Counterfactuals

This appendix reports country-level observed and counterfactual headline inflation series. Each figure aggregates all simulated energy and food price-policy layers available for the country, using the HICP item weights in the country CPI basket.

Table B.1: Price measures included in the national counterfactual simulations

Country	Included price measures	COICOP nents	compo- Assumption window	Input status	
Austria	Electricity cost brake reduced phase: subsidy capped at 15 ct/kWh for 2,900 kWh; Electricity cost brake: 10 ct/kWh base price, subsidy capped at 30 ct/kWh for 2,900 kWh; Electricity excise reduced from 1.5 to 0.1 ct/kWh; Natural-gas excise reduced from 6.6 to 1.196 ct/m3	CP0451, CP0452	2022-05-01–2024-12-01	4 of 4 measures use aggregate-equivalent inputs.	
Belgium	Social energy tariff and basic electricity package; Social energy tariff and basic gas package; Temporary VAT cut on residential electricity from 21% to 6%; Temporary VAT cut on residential natural gas and district heat from 21% to 6%	CP0451, CP0452	2022-03-01–2023-03-01	2 of 4 measures use aggregate-equivalent inputs.	
Croatia	District-heating price freeze; Electricity-price mitigation package; Gas VAT cut and household price subsidy; Household electricity price cap; VAT cut from 13% to 5% on eligible fresh food products	CP0112, CP0114, CP0116, CP0451, CP0455	CP0113, CP0115, CP0117, CP0452,	2022-04-01–2023-12-01	4 of 10 measures use aggregate-equivalent inputs.
Cyprus	Electricity cost subsidy after VAT reduction	CP0451	2022-09-01–2023-02-01	1 of 1 measures use aggregate-equivalent inputs.	
Estonia	100% reimbursement of household gas network fees; 50% reimbursement of electricity network fees; 65% compensation of district-heating increase above October 2021 tariff; Household electricity price compensation; Household natural-gas price compensation	CP0451, CP0455	CP0452, 2021-10-01–2023-03-01	5 of 5 measures use aggregate-equivalent inputs.	
Finland	Temporary 7.5 percentage-point reduction in the biofuel distribution obligation; Temporary electricity VAT reduction from 24% to 10%	CP0451, CP0722	2022-05-01–2023-12-01	1 of 2 measures use aggregate-equivalent inputs.

C The Household Budget Survey in Italy

The most recent complete harmonized Eurostat HBS entry for Italy is 2005. We therefore combine it with the 2015 and 2020 Istat public-use HBS files to construct the household-group baskets.

Age-group baskets are computed directly from the survey-weighted expenditure aggregates in the Istat files, using the age of the household reference person.

For income quintiles, households are ranked by equivalized total consumption using the Carbonaro scale and the survey weights. Because income quintiles are not observed in the target-year files, we transport the relationship between income- and expenditure-quintile baskets observed in 2005. Let E_{jqy} denote expenditure on COICOP group j by expenditure quintile q in year y , and let $s_{jq,2005}^I$ and $s_{jq,2005}^E$ denote the corresponding 2005 shares for income and expenditure quintiles. The estimated income-quintile consumption structure is

$$\hat{s}_{jqy}^I = \frac{E_{jqy} \left(s_{jq,2005}^I / s_{jq,2005}^E \right)}{\sum_k E_{kqy} \left(s_{kq,2005}^I / s_{kq,2005}^E \right)}. \quad (22)$$

Thus, the 2005 income-to-expenditure ratio adjusts each 2015 or 2020 expenditure-quintile component, after which the basket is renormalized to one. A few broad groups are combined to reconcile the two 2005 classifications. The resulting income-quintile structures are estimated rather than directly observed. The procedure addresses the same absence of jointly observed income and consumption discussed by [Donatiello et al. \(2022\)](#).

Table [C.1](#) reports the resulting shares of total consumption. Age shares are direct survey estimates; income-quintile shares are bridge estimates. The first and fifth income quintiles account for about 8 and 39 percent of Italian consumption, respectively.

Table C.1: Expenditures by groups (as a share of total expenditures)

Dimension	Group	2015	2020
Age	Less than 30 years	2.0	2.2
Age	From 30 to 44 years	19.7	17.9
Age	From 45 to 59 years	34.8	34.2
Age	60 years or over	43.5	45.7
Income	First quintile	7.8	8.1
Income	Second quintile	12.7	12.8
Income	Third quintile	17.2	17.0
Income	Fourth quintile	23.3	22.8
Income	Fifth quintile	39.0	39.3

Notes. Entries are percent shares of total annual consumption. Age groups follow harmonised Eurostat HBS bands. Income rows for 2015 and 2020 apply the 2005 income/expenditure-quintile bridge to Istat expenditure-quintile baskets. Sources: Istat HBS public-use files, Eurostat HBS, authors' calculations.

Figure C.3: Price indices by household group, Italy, COICOP digit 3 (index, 1996 = 100)

Notes: The figure reports chained price indices using RAS weighting. Income groups compare the first and fifth quintiles; age groups compare households whose reference person is under 30 with those aged 60 or over.

Sources: Eurostat HICP; Italian HBS inputs described in Appendix C; authors' calculations.

Figure C.4: Inflation by household group, Italy, COICOP digit 3 (in %)

Notes: The figure reports monthly year-on-year inflation rates using RAS weighting for income and age groups.

Sources: Eurostat HICP; Italian HBS inputs described in Appendix C; authors' calculations.

Figure C.5: Contributions to inflation gaps, Italy, COICOP digit 3 (in pp)

(a) Income gap: Quintile 1 minus Quintile 5

(b) Age gap: 60 years or over minus under 30

Notes: Bars decompose the monthly inflation gap into broad consumption components; the black line reports the total gap. Positive values indicate higher inflation for the first group named in each panel.

Sources: Eurostat HICP; Italian HBS inputs described in Appendix C; authors' calculations.

D RAS Weighting

We use the RAS (Row and Column Adjustment Scaling) algorithm. RAS is a bi-proportional matrix scaling method that alternately rescales rows and columns until the required marginal totals are matched ([Bacharach, 1965](#)). In our setting, we combine official HICP item weights with the relative HBS expenditure profile of each household group.

We retain imputed rents in the HBS expenditure profiles even though they are not included in the official HICP. Dropping them before normalizing each group’s expenditures would implicitly treat owner-occupiers as consuming no housing services and would mechanically redistribute the omitted housing share across all remaining items. This is not a neutral rescaling: homeownership, and hence the imputed-rent share, varies systematically across income, age, and residence-area groups. The normalization would therefore inflate the non-housing weights most strongly for groups with high homeownership rates, potentially attributing differences in measured inflation to their consumption patterns when they instead arise from unequal omitted housing shares. [Geerolf \(2023\)](#) shows that this bias can be quantitatively important: because imputed rents are relatively more important for richer, older, and rural households, excluding them can overstate their inflation and can even reverse comparisons between household groups. We therefore preserve imputed rents in the group-level HBS profiles used by the calibration. Their inclusion should be understood as a safeguard against group-specific normalization bias, rather than as a claim that imputed rents belong to the official HICP coverage.

Table [D.1](#) quantifies this sensitivity across countries. The baseline combines HBS actual and imputed rents (041+042) before mapping them to HICP actual rents (041). The first alternative retains only HBS actual rents, while the second removes rents from both the HBS profiles and the HICP basket and renormalizes all remaining items.

Table D.1: Robustness of income-group inflation to the treatment of rents, June 2021–June 2023

Country	HBS 041+042 → HICP 041		HBS 041 → HICP 041		Excluding rents	
	Cumulative inflation	Inflation gap	Cumulative inflation	Inflation gap	Cumulative inflation	Inflation gap
Austria	17.5	0.4	17.1	-0.2	18.3	0.8
Belgium	11.7	-1.1	11.3	-1.6	11.9	-1.1
Croatia	21.1	-0.6	21.1	-0.6	21.3	-0.6
Cyprus	12.7	0.7	12.6	0.6	12.9	0.8
Estonia	38.7	7.5	38.4	7.1	38.8	7.4
Finland	11.5	-1.2	10.0	-3.3	12.8	-0.7
France	12.3	0.2	11.2	-1.3	13.2	0.4
Germany	16.5	1.3	14.7	-1.2	18.4	2.0
Greece	15.1	0.6	14.6	-0.0	15.6	0.8
Ireland	17.2	3.8	17.5	4.4	16.9	4.0
Italy	17.2	2.1	17.2	2.1	17.7	2.3
Latvia	36.0	9.5	36.1	9.6	36.6	9.9
Lithuania	33.6	4.6	33.5	4.5	33.6	4.7
Luxembourg	11.0	-0.2	10.0	-1.5	11.4	-0.2
Malta	13.8	1.6	13.8	1.6	13.0	0.9
Netherlands	17.7	1.2	15.5	-1.7	19.8	2.4
Portugal	13.1	-2.3	12.5	-3.0	13.4	-2.3
Slovakia	26.7	2.7	26.1	2.0	27.3	3.0
Slovenia	19.9	2.4	20.1	2.7	19.7	2.2
Spain	11.8	0.1	11.3	-0.6	12.2	0.2
Euro area	15.2	0.9	14.2	-0.5	16.3	1.3

Notes. Cumulative inflation refers to the first income quintile (Q1); the inflation gap is Q1 minus Q5. The baseline combines HBS actual rents (041) and imputed rents (042) and maps their sum to HICP actual rents (041). The second specification maps only HBS actual rents (041) to HICP 041. The third excludes HBS 041 and 042 as well as HICP 041, and renormalizes the remaining consumption basket. Entries are percentage points, calculated from unrounded indices and rounded to one decimal. Sources: Eurostat, authors' calculations.

We distinguish three objects: the HICP product shares, the aggregate product-by-group expenditure mass calibrated by RAS, and the resulting within-group baskets. First, let $s_{g,y}$ denote the share of group g in total consumption expenditure used for HICP weight year y :

$$s_{g,y} = \frac{E_{g,y'}^{\text{HBS}}}{E_{\text{all},y'}^{\text{HBS}}}, \quad \sum_g s_{g,y} = 1, \quad (23)$$

where y' is the HBS wave matched to HICP weight year y . In the implementation, $s_{g,y}$ is selected from the group consumption-share table using the most recent HBS wave available at or before y ; if no prior wave is available, the earliest available wave is used. These targets are expendi-

ture shares, not population shares. For Italy, the income targets use the Istat-based HBS inputs described in Appendix C.

Let $\mathcal{J}_y$ be the set of matched COICOP categories available in the HICP weighting structure in year y . Let $E_{j,g,y'}^{\text{HBS}}$ denote expenditure on item j by group g in the matched HBS wave y' , and let $E_{j,\text{all},y'}^{\text{HBS}}$ denote expenditure on that item by all households. Consistently with the implementation, the HBS correction factor used in the RAS seed is the share of aggregate expenditure on item j accounted for by group g :

$$c_{j,g,y'}^{\text{HBS}} = \frac{E_{j,g,y'}^{\text{HBS}}}{E_{j,\text{all},y'}^{\text{HBS}}}. \quad (24)$$

Thus $c_{j,g,y'}^{\text{HBS}}$ records how expenditure on item j is distributed across household groups. To avoid mixing index-weight units with expenditure shares, define the HICP weight normalized over the matched product set as

$$\bar{\omega}_{j,y}^{\text{HICP}} = \frac{\omega_{j,y}^{\text{HICP}}}{\sum_{k \in \mathcal{J}_y} \omega_{k,y}^{\text{HICP}}}, \quad \sum_{j \in \mathcal{J}_y} \bar{\omega}_{j,y}^{\text{HICP}} = 1. \quad (25)$$

The initial product-by-group mass is then

$$Z_{j,g,y} = \max \left\{ s_{g,y} \bar{\omega}_{j,y}^{\text{HICP}} c_{j,g,y'}^{\text{HBS}}, \epsilon \right\}, \quad \epsilon = 10^{-12}. \quad (26)$$

The small positive floor is a numerical safeguard to keep the RAS problem strictly non-negative after HICP-HBS matching. RAS transforms this seed into a joint expenditure-share matrix $M_{j,g,y}$. Its group margins equal the groups' expenditure shares, while its product margins equal the normalized HICP shares:

$$\sum_{j \in \mathcal{J}_y} M_{j,g,y} = s_{g,y} \quad \text{for all } g, \quad \sum_g M_{j,g,y} = \bar{\omega}_{j,y}^{\text{HICP}} \quad \text{for all } j. \quad (27)$$

Both sets of margins sum to one, so the constraints are mutually compatible.

The RAS algorithm starts from $M_{j,g,y}^{(0)} = Z_{j,g,y}$ and repeats two scaling steps. At iteration t , the group-margin adjustment is

$$\tilde{M}_{j,g,y}^{(t)} = M_{j,g,y}^{(t-1)} \times \frac{s_{g,y}}{\sum_{\ell \in \mathcal{J}_y} M_{\ell,g,y}^{(t-1)}}, \quad (28)$$

and the product-margin adjustment is

$$M_{j,g,y}^{(t)} = \tilde{M}_{j,g,y}^{(t)} \times \frac{\bar{\omega}_{j,y}^{\text{HICP}}}{\sum_h \tilde{M}_{j,h,y}^{(t)}}. \quad (29)$$

We iterate these two steps by weight year until the maximum absolute row or column marginal error is below 10^{-10} , with a maximum of 1,000 iterations.

The calibrated matrix M is a joint expenditure distribution. The group-specific HICP basket is the corresponding conditional product distribution within group g :

$$\omega_{j,g,y} = \frac{M_{j,g,y}}{s_{g,y}} = \frac{M_{j,g,y}}{\sum_{k \in \mathcal{J}_y} M_{k,g,y}}. \quad (30)$$

The equality of the two denominators follows directly from the group-margin constraint. It implies that each group basket sums to one. Moreover, the expenditure-share-weighted average of the group baskets reproduces the normalized HICP product weights:

$$\sum_{j \in \mathcal{J}_y} \omega_{j,g,y} = 1, \quad \sum_g s_{g,y} \omega_{j,g,y} = \bar{\omega}_{j,y}^{\text{HICP}}. \quad (31)$$

The package implements the same system on a percentage scale. Internally, the calibrated mass is $M_{j,g,y}^{\text{pct}} = 100M_{j,g,y}$, so its margins are $100s_{g,y}$ and $100\bar{\omega}_{j,y}^{\text{HICP}}$. The package returns these percentage weights in the R variable `weighted_consumption`. Denoting this variable by $w_{j,g,y}^{\text{code}}$, we have

$$w_{j,g,y}^{\text{code}} = \frac{M_{j,g,y}^{\text{pct}}}{s_{g,y}} = 100\omega_{j,g,y}, \quad (32)$$

and sums to 100 within every household group. Thus division by $s_{g,y}$ in the code is the percentage-scale counterpart of dividing $M_{j,g,y}$ by its group-row sum in the normalized mathematical representation.

This preserves the relative information contained in the HBS expenditure profiles while making the aggregate of the household-group baskets consistent with the published HICP weighting structure, up to residual differences induced by product coverage and COICOP matching.

Table D.2 compares the two weights for Germany at COICOP digit 3 over the period beginning in 2019. The RAS calibration tracks the published German HICP more closely than the relative-expenditure weighting, whose implicit aggregate weights are equal across groups.

Table D.2: Germany HICP validation by weighting scheme (differences in pp)

Method	Obs.	Mean diff.	Mean abs. diff.	RMSE	Max abs. diff.
RAS	88	-0.059	0.093	0.118	0.259
Relative expenditure	88	-0.070	0.143	0.166	0.449

Notes: Validation statistics compare the recalculated average of German income-quintile inflation rates with the published all-items HICP inflation rate. The sample is monthly, from January 2019 to April 2026. All differences are recalculated minus published inflation and are reported in percentage points.

E Validation Tests

This appendix reports three validation checks for the recalculated French inflation series: agreement with published HICP, aggregation of quintile inflation rates, and comparison with official INSEE decile inflation.

E.1 Internal Consistency

Figure E.1 compares COICOP digit-3 RAS recalculated French inflation with published all-items HICP. Figure E.2 compares the total inflation rate with the expenditure-weighted average of income-quintile inflation rates.

Figure E.1: Internal consistency: France total inflation and published HICP, COICOP digit 3 RAS (in %)

Notes: Blue line: published all-items HICP. Black line: recalculation from 2019 onward. Grey bars: recalculation minus published HICP, in points.

Sources: INSEE, Eurostat, authors' calculations.

Figure E.2: Internal consistency: France total inflation and weighted average of quintiles, COICOP digit 3 RAS (in %)

Notes: Recalculated total inflation and the weighted average of recalculated income-quintile inflation rates. Grey bars: weighted average minus total, in points.

Sources: INSEE, Eurostat, authors' calculations.

E.2 External Consistency

Figure E.3 compares the annualized inflation rates computed at COICOP digit 4 with the official INSEE income decile series.

Figure E.3: External consistency: annual inflation by standard-of-living decile, France (in %)

Notes: Official INSEE annual inflation rates by standard-of-living decile are compared with the recalculated series.

Sources: INSEE, Eurostat, authors' calculations.
